Directed by: Professor Brian N. Levine

In this thesis, I analyze and improve the security and performance of blockchain systems across three primary themes. In the first theme, I analyze blockchain algorithms for setting block discovery difficulty. Unfortunately, churn in mining power can cause uneven inter-block delays when the difficulty is not set accurately. Mining power can change due to many reasons, including the miners' allocation of hardware and swings in the exchange rate of a currency. For example, Bitcoin Cash has seen enormous variance in mining power since its creation and the existing algorithm for difficulty did not easily converge. I propose two alternatives to accurately update difficulty: one that solely uses information that is currently available in blockchain networks, and another based on status reports regularly broadcast from some or all miners of their partial proof-of-work (POW). Status reports can also be used for emergency difficulty adjustment, an algorithm the network resorts to when a block takes unusually long to discover.

iv

Status reports add overhead into networks because they require the broadcast of additional information. In a second theme, I introduce a novel method of interactive set reconciliation for the distribution of status reports in order to reduce traffic. Even without status reports, this protocol works for the efficient distribution of blocks. The approach, called Graphene, couples a Bloom filter with an IBLT. Then I evaluate performance analytically and show that Graphene blocks are always smaller and therefore network performance is improved.

In the third theme, I analyze the practical feasibility of double-spend and selfish mining attacks on blockchain systems. The hash rate of miners is the primary quantitative factor that determines the security of any POW based blockchain consensus algorithm. Most analyses generally assume that the hash rate of honest and malicious miners is known. However, I show that hash rate estimation is difficult and introduces high variance. Therefore, I argue that these double-spend and selfish mining attacks are difficult to carry out with high precision, and use reinforcement learning techniques to realistically evaluate these attacks when an attacker does not have full knowledge of the networks mining power.

#### CHAPTER 1

#### OVERVIEW OF BLOCKCHAIN SYSTEMS

#### 1.1 Basic Operation

Account balances. A Bitcoin is a unit of currency, which is fungible, divisible (up to eight decimal places), and recombinable. It is measured as a balance across multiple accounts, which are themselves manifested in *addresses*.<sup>1</sup> Each address comprises a stored asymmetric cryptographic key and an associated balance of Bitcoin. The public portions of an address are the public key and the balance of coin. When an address is involved in a *transaction* with one or more other addresses, Bitcoins are transferred among them.

Roles. Users wishing to exchange coins broadcast the details of their transactions over Bitcoin's p2p network, signed with their private keys. A set of miners on the p2p network verify that each transaction is signed correctly and does not conflict with another transaction. Miners independently agglomerate a set of valid transactions into a block and attempt to solve a predefined proof-of-work (POW) problem involving this block and a chain of prior valid blocks. In Bitcoin, the POW computation is dynamically calibrated to take approximately ten minutes per block. The first miner to solve the problem broadcasts his solution to the network, adding it to the evergrowing blockchain; the miners then start over, with the appended blockchain and the set of transactions that were not added as part of the previous block. When transactions appear in a block, they are considered confirmed, and each subsequent

<sup>&</sup>lt;sup>1</sup>Internally, Bitcoins exist only as "unspent transaction outputs" (UTXO), but users of the system think of them as balances in addresses, and that view does not affect the results of this paper.

block provides additional confirmation. The miners' incentive for discovering a block is a reward of coins, called the *coinbase*, consisting of a predetermined *block reward* (currently 12.5 BTC) and fees from transactions included in the block.

Full nodes are peers in the network that do not mine, but do generate, validate, and propagate transactions and blocks to other nodes including miners. Consumers (i.e., those who purchase goods or services) typically have no need to process and validate all transactions, so they can instead operate simple payment verification (SPV) nodes that process, store, and transmit data involving only addresses-of-interest, which are typically addresses they control, make payments to, or receive payments from. SPV nodes rely on full nodes to relay transactions-of-interest.

Bitcoin transaction consistency. The main goal of the Bitcoin p2p network is to provide a consistent view of blocks and unconfirmed transactions across all network peers. Each peer maintains a local snapshot of the transactions in a memory pool dubbed the *mempool*. Blocks consist of a list of transactions that have already (almost always) been broadcast to miners and full nodes in the network.

To announce a new block, a miner lists all transactions contained in the new block along with a header that provides an easily verifiable *proof-of-work* (POW) solution. When a full node or miner receives a new block, it validates each transaction in the block and the proof of work.

Due to propagation delays in the network, it is possible for the miners to receive competing (but valid) block announcements, which bifurcates the chain, until one of the two forks is appended to first. It is also possible and valid for a miner to receive a set of blocks that retroactively rewrites many blocks; doing so is a demonstration of computational work that miners accept despite the age or depth<sup>2</sup> of a rewritten block.

 $<sup>^{2}</sup>$ The depth of a block refers to the number of blocks that follow it; the height of a block is the number of blocks that precede it.

Topology and flooding. Bitcoin propagates new transaction and block announcements by flooding throughout a p2p random graph of full nodes and miners. Each peer in the graph requests direct connections to 8 other peers, and accepts requests for connections from up to 117 other peers. A peer will offer a newly created transaction to each neighbor via an invmessage, which reports the hash of the transaction content as its ID. If a peer does not already possess the transaction, it will request it using a getdata message. Blocks are handled similarly: invmessages describe a block by its ID, which is created from the hash of the block's contents. Upon receiving the inv, peers will request the block if they do not already have it. Hence, in today's topology, invmessages cross every edge in the random graph once, while the actual transaction and block data typically propagate along only a spanning tree of the graph (more edges will be traversed if there are propagation delays). For convenience, in this paper, we refer to the set of (unconfirmed) transaction IDs that a peer knows about as the *IDpool*. Actual transaction contents are placed in the mempool.

#### CHAPTER 2

#### DIFFICULTY ESTIMATION

#### 2.1 Problem Statement

I analyze a blockchain systems algorithm for setting block discovery difficulty. Difficulty is updated glacially in most systems (e.g., every two weeks in Bitcoin). However, the of churn of mining power can cause problems when the difficulty is not set often. Mining power can change due to miners' updating to new hardware, diurnal changes in electricity rates, or swings in the exchange rate of a currency. For example, Bitcoin Cash has seen enormous variance in mining power since its creation. I propose two alternatives to accurately update difficulty: one that solely uses information that is currently available in blockchain networks, and another based on status reports regularly broadcast from some or all miners of their partial proof-of-work (POW). Status reports can also be used for emergency difficulty adjustment, an algorithm the network resorts to when a block takes unusually long to discover.

#### 2.2 Preliminary Work

#### 2.2.1 Analysis of Difficulty Estimation

Algorithm for setting difficulty. Bitcoin's difficulty starts at 1. Then for every 2016 blocks that are found, the timestamps of the blocks are compared to find out how much time it took to find 2016 blocks. Let t denote the time in minutes it took to find 2016 blocks. Because want 2016 blocks to take 2 weeks (20160 minutes), we multiply the old difficulty by 20160/t. If the correction factor is greater than 4 (or less than 1/4), then 4 or 1/4 are used instead, to prevent the change from being too abrupt.

Bitcoin's target and difficulty are related to each other as follows: target = targetmax / difficulty =  $2^{224}/D_t$  (http://learnmeabitcoin.com/guide/difficulty). The difficulty and target are inversely proportional: 1) When difficulty increases, the target decreases. 2) When difficulty decreases, the target increases. Therefore, a smaller target makes block creation more difficult: as the difficulty goes up, so does the expected time needed to create a block.

Bitcoin's Difficulty Adjustment. Let  $D_i$  denote the *i*th time the difficulty is set, and X denote the total number of minutes it took to generate n blocks after  $D_i$  is set. Furthermore, let  $X_x$  denote the number of minutes it took to generate the xth block after  $D_i$  is set. Then we have

$$D_{i+1} = D_i \frac{10n}{X} \tag{2.1}$$

$$D_i = D_i \frac{10n}{\sum_{x=1}^i X_x}$$
 (2.2)

Let D be the sequence generated by the last equation where the first element of the sequence is  $D_0 = 1$ . Note that each X is created such that  $X = \sum_{x=1}^{n} X_x$ , where  $X_x \sim \text{Exp}(\beta)$ , assuming that the hash rate stays constant for the 2-week period after  $D_i$  is set. (An exponential describes the time between events in a Poisson process, i.e. a process in which events occur continuously and independently at a constant average rate).

$$D_{i+1} = f(D_i, X_1, \dots, X_n) = 10nD_i \left(\frac{1}{\sum_{x=1}^n X_x}\right)$$
 (2.3)

$$=10nD_i\frac{1}{V}\tag{2.4}$$

Understanding the Relationship Between Hash Rate and  $\beta$ . Given difficulty  $D_i$ , the expected number of hashes, h, needed to meet the target for a block is

$$\mathbb{E}[h] = \frac{2^{256} - 1}{T_i} = \frac{2^{256} - 1}{2^{224}/D_i} = \frac{D_i(2^{256} - 1)}{2^{224}}$$
 (2.5)

However,  $\mathbb{E}[h]$  describes the *total* number of expected hashes needed to find a block. We have observations regarding the *time* it takes to generate a block. Let r be the hash rate of the network in minutes (or the number of hashes per time unit), and  $X = X_1, \ldots, X_n$ , where  $X \sim \text{Exp}(\beta)$ , where  $\beta = 1/\lambda$ . Note that  $\lambda r$  is the expected number of hashes each time a block is created.

$$\mathbb{E}[h] = r\lambda = r\frac{1}{\beta} \tag{2.6}$$

$$r = \mathbb{E}[h]\beta \tag{2.7}$$

Adjusting Difficulty Accurately. For Bitcoin, where the network is expected to solve a block every 10 mins, we can adjust the target for the i + 1th time as follows

$$\frac{(2^{256} - 1)}{T_{i+1}} = 10r\tag{2.8}$$

$$=\frac{10(2^{256}-1)\beta}{T_i}\tag{2.9}$$

$$T_{i+1} = \frac{T_i}{10\beta} \tag{2.10}$$

Therefore, we can adjust the difficulty for the i + 1th time as follows

$$D_{i+1} = \frac{2^{224}}{T_{i+1}} \tag{2.11}$$

$$=\frac{2^{224}10\beta}{T_i}\tag{2.12}$$

$$=\frac{2^{224}10\beta}{2^{224}/D_i}\tag{2.13}$$

$$=10\beta D_i \tag{2.14}$$

**Expected Value of Difficulty.** We can talk about the expected value of a term in a sequence given its preceding term and the new data we see.

$$\mathbb{E}[D_{i+1}|D_i, X_1, \dots, X_n] = \mathbb{E}\left[10nD_i\frac{1}{Y}\right]$$
(2.15)

$$=10nD_i \mathbb{E}\left[\frac{1}{Y}\right] \tag{2.16}$$

$$=10nD_i\left(\frac{1}{\beta(n-1)}\right) \tag{2.17}$$

$$=\frac{10nD_i}{\beta(n-1)}\tag{2.18}$$

Refer to https://stats.stackexchange.com/questions/139467/expected-value-of-y-1-x-wh for proof.

Variance of Difficulty. Additionally, we can also talk about the variance of a term in a sequence with respect to its preceding term.

$$\operatorname{Var}(D_{i+1}|D_i, X_1, \dots, X_n) = \operatorname{Var}\left(10nD_i\frac{1}{Y}\right)$$
(2.19)

$$= (10nD_i)^2 \operatorname{Var}\left(\frac{1}{Y}\right) \tag{2.20}$$

$$= (10nD_i)^2 \left(\frac{1}{\beta^2(n-1)^2(n-2)}\right)$$
 (2.21)

$$=\frac{(10nD_i)^2}{\beta^2(n-1)^2(n-2)}\tag{2.22}$$

Refer to https://www.johndcook.com/inverse\_gamma.pdf and https://ocw.mit.
edu/courses/mathematics/18-443-statistics-for-applications-fall-2006/lecture-notes
lecture6.pdf for explanation.

#### Bias of Difficulty.

$$bias(D_{i+1}|D_i, X_1, ..., X_n) = \mathbb{E}[D_{i+1}|D_i, X_1, ..., X_n] - D_{i+1}$$
(2.23)

$$= \frac{10nD_i}{\beta(n-1)} - 10\beta D_i \tag{2.24}$$

Mean Squared Error (MSE) of Difficulty. For any random variable X, the MSE is  $MSE(X) = bias(X)^2 + Var(X)$ .

$$MSE(D_{i+1}|D_i, X_1, ..., X_n) = bias(D_{i+1}|D_i, X_1, ..., X_n)^2 + Var(D_{i+1}|D_i, X_1, ..., X_n)$$
(2.25)

$$= \left(\frac{10nD_i}{\beta(n-1)} - 10\beta D_i\right)^2 + \frac{(10nD_i)^2}{\beta^2(n-1)^2(n-2)}$$
 (2.26)

#### 2.2.2 Alternative Estimation

In this section, we describe two blockchain-only methods of estimating miner hash rates. Although these approaches have no additional network costs and do not require cooperation from miners, they are less accurate than status reports. We then extend our techniques to allow for hash rate estimation of an individual or a subset of miners. As we show, this extension allows for the incremental deployment of status reports.

We would like to estimate the network hash rate,  $\hat{h}$ , using only the *inter-arrival* time of mined blocks. Let  $\mathbf{X} = X_1, \dots, X_n$  denote the inter-arrival time between n+1 consecutive blocks on the blockchain.

Mining is an example of a Poisson process because, under constant mining power, blocks are mined continuously and independently at a constant average rate. Therefore,  $X_i \sim \text{Expon}(\gamma)$  with  $\gamma = 1/\lambda$ . In this parametrization of the exponential,  $\gamma$  represents the survival parameter, and hence, the *expected time* it takes for a block to arrive. Ideally, in Bitcoin  $\gamma = 10$  minutes, in Ethereum  $\gamma = 15$  seconds.

Estimator for  $\gamma$ , the expected inter-arrival time between blocks. Given a consecutive sequence of n+1 blocks, n inter-arrival times can be computed by subtracting the timestamp of each block from that of its preceding block. It it well known that the unbiased MLE estimator for  $\gamma$  is

$$\hat{\gamma} = \sum_{i=1}^{n} X_i / n. \tag{2.27}$$

Estimating hash rate from  $\tilde{\gamma}$ . Since a block is created when a miner produces a hash smaller than the target, we can calculate the expected number of hashes needed to create a block based on the current difficulty, D, of blocks and the current target, t. For Bitcoin and Ethereum, this value is  $E[\theta] = 2^{256}/t = 2^{32}D$ . For a constant hash rate, h, in expectation, it must be that  $E[Xh] = E[\theta]$  and therefore,  $h = E[\theta]/E[X]$ . Because  $E[X] = \gamma$ , it must be that the true hash rate of the network is  $h = E[\theta]/\gamma$ . Note that we do not know the true value of  $\gamma$ , but can estimate it given the interarrival time of blocks we have observed. Therefore, the estimated hash rate of the network is

$$\hat{h} = \frac{E[\theta]}{\hat{\gamma}} = \frac{2^{32}D}{\hat{\gamma}}.\tag{2.28}$$

Note that we do not know  $\beta$  (we know what it *should* be), but can estimate it given the blocks we have observed.

Parametrization and Estimation of  $\beta$ . Let  $X = X_1, \dots, X_n$ , where  $X \sim \text{Exp}(\beta)$ , where  $\beta = 1/\lambda$ . The MLE estimator for  $\beta$  is

$$\hat{\beta} = \frac{\sum_{i=1}^{n} X_i}{n} \tag{2.29}$$

The expected value of the estimator is

$$\mathbb{E}[\hat{\beta}|\beta] = \frac{1}{n} \mathbb{E}\left[\sum_{i=1}^{n} X_i\right]$$
 (2.30)

$$=\frac{1}{n}n\beta\tag{2.31}$$

$$=\beta \tag{2.32}$$

$$\mathbb{E}[\hat{\beta}^2|\beta] = \mathbb{E}\left[\frac{\left(\sum_{i=1}^n X_i\right)^2}{n^2}\right]$$
 (2.33)

$$= \frac{1}{n^2} \mathbb{E}\left[\left(\sum_{i=1}^n X_i\right)^2\right] \tag{2.34}$$

$$=\frac{1}{n^2}(n^2\beta^2 + n\beta^2) \tag{2.35}$$

$$=\beta^2 + \frac{\beta^2}{n} \tag{2.36}$$

$$\mathbb{E}\left[\frac{1}{\hat{\beta}}\middle|\beta\right] = \mathbb{E}\left[\frac{1}{\sum_{i=1}^{n} X_i/n}\middle|\beta\right] \tag{2.37}$$

$$= \mathbb{E}\left[\frac{n}{\sum_{i=1}^{n} X_i} \middle| \beta\right] \tag{2.38}$$

$$= n \mathbb{E}\left[\frac{1}{\sum_{i=1}^{n} X_i}\right] \tag{2.39}$$

$$=\frac{n}{\beta(n-1)}\tag{2.40}$$

Refer to https://www.johndcook.com/inverse\_gamma.pdf for details on eq. 39.

This estimator is *not* biased. The bias is

$$\operatorname{bias}(\hat{\beta}) = \mathbb{E}[\hat{\beta}|\beta] - \beta \tag{2.41}$$

$$= \beta - \beta \tag{2.42}$$

$$=0 (2.43)$$

The variance of the estimator is

$$Var(\hat{\beta}) = Var\left(\frac{\sum_{i=1}^{n} X_i}{n}\right)$$
 (2.44)

$$= \frac{1}{n^2} \operatorname{Var}\left(\sum_{i=1}^n X_i\right) \tag{2.45}$$

$$=\frac{1}{n^2}n\beta^2\tag{2.46}$$

$$=\frac{1}{n}\beta^2\tag{2.47}$$

Ideally, in Bitcoin  $\beta = 1/10$  mins and in Ethereum  $\beta = 1/15$  secs. Note that the variance increases with more data (more inter-arrival times).

Adjusting Difficulty Using Time-Based Hash Rate Estimator. For Bitcoin, where the network is expected to solve a block every 10 mins, we can adjust the difficulty for the i + 1th time as follows

$$\frac{D_{i+1}(2^{256} - 1)}{2^{224}} = 10r (2.48)$$

$$\frac{D_{i+1}(2^{256} - 1)}{2^{224}} = \frac{10D_i(2^{256} - 1)\hat{\beta}}{2^{224}}$$
 (2.49)

$$D_{i+1} = 10D_i\hat{\beta} \tag{2.50}$$

Expected Value of New Difficulty.

$$\mathbb{E}[D_{i+1}|D_i, X_1, \dots, X_n] = \mathbb{E}[10D_i\hat{\beta}] \tag{2.51}$$

$$=10D_i \mathbb{E}[\hat{\beta}] \tag{2.52}$$

$$=10D_i\beta\tag{2.53}$$

Variance of New Difficulty.

$$Var(D_{i+1}|D_i, X_1, \dots, X_n) = Var(10D_i\hat{\beta})$$
 (2.54)

$$= (10D_i)^2 \operatorname{Var}(\hat{\beta}) \tag{2.55}$$

$$=\frac{(10D_i\beta)^2}{n}\tag{2.56}$$

Bias of New Difficulty.

$$bias(D_{i+1}|D_i, X_1, ..., X_n) = \mathbb{E}[D_{i+1}|D_i, X_1, ..., X_n] - D_{i+1}$$
(2.57)

$$=10D_i\beta - 10D_i\beta \tag{2.58}$$

$$=0 (2.59)$$

#### MSE of New Difficulty.

$$MSE(D_{i+1}|D_i, X_1, ..., X_n) = bias(D_{i+1}|D_i, X_1, ..., X_n)^2 + Var(D_{i+1}|D_i, X_1, ..., X_n)$$
(2.60)

$$=\frac{(10D_i\beta)^2}{n}\tag{2.61}$$

#### Comparison of Estimators 2.2.3

Variance. Low variance is favorable. How does the variance our estimator (LHS) compare to the original estimator (RHS)?

$$\frac{(10D_i\beta)^2}{n} \le \frac{(10nD_i)^2}{\beta^2(n-1)^2(n-2)}$$

$$\frac{\beta^2}{n} \le \frac{n^2}{\beta^2(n-1)^2(n-2)}$$
(2.62)

$$\frac{\beta^2}{n} \le \frac{n^2}{\beta^2 (n-1)^2 (n-2)} \tag{2.63}$$

This equation holds for n > 2 and  $0 < \beta < 1$ .

#### Mean Squared Error.

$$\frac{(10D_i\beta)^2}{n} \le \left(\frac{10nD_i}{\beta(n-1)} - 10\beta D_i\right)^2 + \frac{(10nD_i)^2}{\beta^2(n-1)^2(n-2)}$$
 (2.64)

This equation holds for n > 2,  $0 < \beta < 1$  and  $D_i \in \mathcal{R}$ .

So, time-based estimator is indeed better.

#### 2.3 **Proposed Work**

#### CHAPTER 3

#### **GRAPHENE**

#### 3.1 Background

In this section, we review the operation of IBLTs and summarize related work.

#### 3.1.1 Overview of IBLTs

Overview of IBLTs. We make use of Invertible Bloom Lookup Tables (IBLTs) [10], which is an efficient data structure for set reconciliation between two peers. Like Bloom filters [3], IBLTs allow two parties to determine, with high probability, which values from a set they share in common. But unlike Bloom filters, IBLTs enable the recovery of any missing values, which are assumed to be of fixed size and encoded as binary strings. Key-value pairs can be inserted, retrieved and deleted like an ordinary hash table. An IBLT consists of m entries, each storing a count, a keySum, and a valueSum, all initialized to zero.

A new value v is inserted into location i = h(v) based on the hash of its value such that i < m. At entry i, all three fields are incremented or xored. IBLTs use k > 1 hash functions to store each value in k entries, which we collectively call a value's entry set. If table space is sufficient, then with high probability for at least one of the k entries, count  $\equiv 1$ .

Suppose that two peers each have a list of values, V and V', respectively, such that the difference is expected to be small. The first peer constructs an IBLT L (with m entries) from V. The second peer constructs V' from L' (also having m entries). Eppstein et al. [6] showed that a cell-by-cell difference operator can be

used to efficiently compute the symmetric difference  $L \triangle L'$ . For each pair of fields (f, f'), at each entry in L and L', we compute either  $f \oplus f'$  or f - f' depending on the field type. When  $|\mathsf{count}| \equiv 1$  at any entry, the corresponding value can be recovered. Peers proceed by removing the recoverable key-value pair from all entries in the value's entry set. This process will generally produce new recoverable entries, and continues until nothing is recoverable.

#### 3.1.2 Related Work

The main limitation we are addressing with Graphene is the inefficiency of blockchain systems in disseminating block data. A block announcement must be validated using the transaction content comprising the block. However, it is likely that the majority of the peers have already received these transactions, and they only need to discern them from those in their mempool. In principle, a block announcement needs to include only the IDs of those transactions, and accordingly, Corallo's Compact Block design [5] — which has been recently deployed — significantly reduces block size by including a transaction ID list at the cost of increasing coordination to 3 roundtrip times. We further detail Compact Block's operation in Section ?? and compare it quantitatively in Section ??. Xtreme Thinblocks [18], an alternative protocol, works similarly to Compact Blocks but has greater data overhead. Specifically, if an invis sent for a block that is not in the receiver's mempool, the receiver sends a Bloom filter of her IDpool along with the request for the missing block. As a result, Xtreme Thinblocks are larger than Compact Blocks but require just 2 roundtrip times. Relatedly, the community has discussed in forums the use of IBLTs (alone) for reducing block announcements [1,15], but these schemes have not been formally evaluated and are less efficient than our approach. Our novel method, which we prove and demonstrate is smaller than all of these recent works, requires just 2 roundtrip times for coordination.

#### 3.2 Graphene: Efficient Block Announcements

In this section, we detail Graphene, where a receiver learns the set of specific transaction IDs that are contained in a (pending or confirmed) block containing n transactions. Unlike other approaches, Graphene never sends an explicit list of transaction IDs, instead it sends a small Bloom filter and a very small IBLT.

#### PROTOCOL 1: Graphene

1: Sender: Sends *inv* for a block.

2: Receiver: Requests unknown block; includes count of txns in her IDpool, m.

3: Sender: Sends Bloom filter S and IBLT  $\mathcal{I}$  (each created from the set of n txn IDs in the block) and essential Bitcoin header fields. The FPR of the filter is  $f = \frac{a}{m-n}$ , where  $a = n/(c\tau)$ .

4: Receiver: Creates IBLT  $\mathcal{I}'$  from the txn IDs that pass through  $\mathcal{S}$ . She decodes the *subtraction* [6] of the two blocks,  $\mathcal{I} \triangle \mathcal{I}'$ .

#### 3.2.1 The Protocol

The intuition behind Graphene is as follows. The sender creates an IBLT  $\mathcal{I}$  from the set of transaction (txn) IDs in the block. To help the receiver create the same IBLT (or similar), he also creates a Bloom filter  $\mathcal{S}$  of the transaction IDs in the block. The receiver uses  $\mathcal{S}$  to filter out transaction IDs from her pool of received transaction IDs (which we call the IDpool) and creates her own IBLT  $\mathcal{I}'$ . She then attempts to use  $\mathcal{I}'$  to  $\operatorname{decode} \mathcal{I}$ , which, if successful, will yield the transaction IDs comprising the block. The number of transactions that falsely appear to be in  $\mathcal{S}$ , and therefore are wrongly added to  $\mathcal{I}'$ , is determined by a parameter controlled by the sender. Using this parameter, he can create  $\mathcal{I}$  such that it will decode with very high probability.

A Bloom filter is an array of x bits representing y items. Initially, the x bits are cleared. Whenever an item is added to the filter, k bits, selected using k hash functions, in the bit-array are set. The number of bits required by the filter is  $x = \frac{1}{2} \left( \frac$ 

 $y = \frac{\ln(f)}{\ln^2(2)}$ , where f is the intended false positive rate (FPR). For Graphene, we set  $f = \frac{a}{m-n}$ , where a is the expected difference between  $\mathcal{I}$  and  $\mathcal{I}'$ . Since the Bloom filter contains n entries, and we need to convert to bytes, its size is  $\frac{-\ln(\frac{a}{m-n})}{\ln^2(2)}\frac{1}{8}$ . It is also the case that a is the primary parameter of the IBLT size. IBLT  $\mathcal{I}$ can be decoded by IBLT  $\mathcal{I}'$  with very high probability if the number of cells in  $\mathcal{I}$  is d-times the expected symmetric difference between the list of entries in  $\mathcal{I}$  and the list of entries in  $\mathcal{I}'$ . In our case, the expected difference is a, and we set d=1.5 (see Eppstein et al. [6], which explores settings of d). Each cell in an IBLT has a count, a hash value, and a stored value. (It can also have a key, but we have no need for a key). For us, the count field is 2 bytes, the hash value is 4 bytes, and the value is the last 5 bytes of the transaction ID (which is sufficient to prevent collisions). In sum, the size of the IBLT with a symmetric difference of a entries is 1.5(2+4+5)a = 16.5abytes. Thus the total cost in bytes, T, for the Bloom filter and IBLT are given by  $T(a) = n \frac{-\ln(f)}{c} + a\tau = n \frac{-\ln(\frac{a}{m-\mu})}{c} + a\tau$ , where all Bloom filter constants are grouped together as  $c = 8 \ln^2(2)$ , and we let the overhead on IBLT entries be the constant  $\tau = 16.5.$ 

To set the Bloom filter as small as possible, we must ensure that the FPR of the filter is as high as permitted. If we assume that all invmessages are sent ahead of a block, we know that the receiver already has all of the transactions in the block in her IDpool (they need not be in her mempool). Thus,  $\mu = n$ ; i.e., we allow for a of m-n transactions to become false positives, since all transactions in the block are already guaranteed to pass through the filter. It follows that

$$T(a) = n \frac{-\ln(\frac{a}{m-n})}{c} + a\tau. \tag{3.1}$$

Taking the derivative w.r.t. a, Eq. 3.1 is minimized<sup>1</sup> when when  $a = n/(c\tau)$ .

Due to the randomized nature of an IBLT, there is a non-zero chance that it will fail to decode. In that case, the sender resends the IBLT with double the number of cells (which is still very small). In our simulations, presented in the next section, this doubling was sufficient for the incredibly few IBLTs that failed.

#### PROTOCOL 2: CompactBlocks

- 1: Sender: Sends invfor a block that has n txns.
- 2: Receiver: If block is not in mempool, requests compact block.
- 3: Sender: Sends the block header information, all txn IDs in the block and any full txns he predicts the sender hasn't received yet.
- 4: Receiver: Recreates the block and requests missing txns if there exist any.

#### 3.2.2 Comparison to Compact Blocks.

Compact Blocks [5] is to our knowledge the best-performing related work. It has several modes of operation. We examined the Low Bandwidth Relaying mode due to its bandwidth efficiency, which operates as follows. After fully validating a new block, the sender sends an inv, for which the receiver sends a getdata message if she doesn't have the block. The sender then sends a compact block that contains block header information, all transaction IDs (shortened to 5 bytes) in the block, and any transactions that he predicts the receiver does not have (e.g., the coinbase). If the receiver still has missing transactions, she requests them via an invmessage.

$$T(a) = \left( \lceil \ln(\frac{m-n}{a}) \rceil \left\lceil \frac{n \ln(\frac{m-n}{a})}{\lceil \ln(\frac{m-n}{a}) \rceil \ln^2(2)} \right\rceil \right) \frac{1}{8} + \lceil a \rceil \tau. \tag{3.2}$$

The optimal value of Eq. 3.2 can be found with a simple brute force loop. We compared the value of a picked by using  $a = n/(c\tau)$  to the cost for that a from Eq. 3.2, for valid combinations of  $50 \le n \le 2000$  and  $50 \le m \le 10000$ . We found that it is always within 37% of the cost of the optimal value from Eq. 3.2, with a median difference of 16%. In practice, a for-loop brute-force search for the lowest value of a is almost no cost to perform, and we do so in our simulations.

<sup>&</sup>lt;sup>1</sup>Actual implementations of Bloom filters and IBLTs involve several (non-continuous) ceiling functions such that we can re-write:

Protocol 2 outlines this mode of Compact Blocks. The main difference between Graphene and Compact Blocks is that instead of sending a Bloom filter and an IBLT, the sender sends block header information and all shortened transaction IDs to the receiver.

A detailed example of how to calculate the size of each scheme is below; but we can state more generally the following result. For a block of n transactions, Compact Blocks costs 5n bytes. For both protocols, the receiver needs the invmessages for the set of transactions in the block before the sender can send it. Therefore, we expect the size of the IDpool of the receiver, m, to be constrained such that  $m \geq n$ . Assuming that m > 0 and n > 0, the following inequality must hold for Graphene to outperform Compact Blocks:

$$n\frac{-\ln(\frac{a}{m-n})}{c} + a\tau < 5n \tag{3.3}$$

$$n > m/1287670$$
 (3.4)

In other words, Graphene is strictly more efficient than Compact Blocks unless the set of unconfirmed transactions held by peers is 1,287,670 times larger than the block size (e.g., over 22 billion unconfirmed transactions for the current block size.) Finally, we note that Xtreme Thinblocks [18] are strictly larger than Compact Blocks since they contain all IDs and a Bloom filter, and therefore Graphene performs strictly better than Xtreme Thinblocks as well. In Section ??, we provide specific empirical results from network simulation, where we use real IBLTs and Bloom filters to evaluate Graphene and Compact Blocks.

**Example.** A receiver with an IDpool of m=4000 transactions makes a request for a new block that has n=2000 transactions. The value of a that minimizes the cost is  $a=n/(c\tau)=31.5$ . The sender creates a Bloom filter  $\mathcal{S}$ with  $f=\frac{a}{m-n}=31.5/2000=0.01577$ , with total size of  $2000\times\frac{-ln(0.01577)}{c}=2.1$  KB. The sender also creates an IBLT

with a cells, totaling 16.5a = 521B. In sum, a total of 2160B + 521B = 2.6 KB bytes are sent. The receiver creates an IBLT of the same size, and using the technique introduced in Eppstein et al. [6], the receiver subtracts one IBLT from the other before decoding. In comparison, for a block of n transactions, Compact Blocks costs  $2000 \times 5B = 10$  KB, over 3 times the cost of Graphene.

**Ordered blocks.** Graphene does not specify an order for transactions in the blocks, and instead assumes that transactions are sorted by ID. Bitcoin requires transactions depending on another transaction in the same block to appear later, but a canonical ordering is easy to specify. If a miner would like to order transactions with some proprietary method (e.g., [11]), that ordering would be sent alongside the IBLT. For a block of n items, in the worst case, the list will be  $n \log_2(n)$  bits long. Even with this extra data, our approach is much more efficient than Compact Blocks. In terms of the example above, if Graphene was to impose an ordering, the additional cost for n = 2000 transactions would be  $n \log_2(n)$  bits  $= 2000 \times log_2(2000)$  bits = 2.74 KB. This increases the cost of Graphene to 5.34 KB, still almost half of Compact Blocks.

#### 3.2.3 Empirical Evaluation

#### CHAPTER 4

#### RL APPLIED TO BITCOIN

#### 4.1 Background

#### 4.1.1 Selfish Mining and Double-Spend Attacks

Blockchain systems [13] provide probabilistic consensus [19] among a set of peers on the order and validity of a set of blocks, each containing transactions. The blockchain encodes the consensus as the *main chain* among all possible forks. As the *depth* of a block on the main chain increases, there is an exponentially decreasing probability that network consensus will switch the main chain to a fork that does not include the block [8,13]. This result assumes that the attacker never stops mining on the alternative fork, regardless of cost. A more realistic model assumes that attackers have finite time and resources, and would not expend resources on an attack that isn't expected to be profitable.

Recently, Gervais et al. [9] evaluated the security of blockchains in terms of an attacker's economic profitably and assuming finite resources. They modeled a double-spending attacker's strategy as Markov Decision Process. MDPs are defined by a finite set of discrete states, a set of actions, a transition function, and a reward function. They defined each state in the MDP as a tuple representing the status of the fork, and the number of blocks mined by an attacker, the honest miners, and eclipse attack victim [12], respectively. Gervais et al. encoded several factors into the MDP that affect attacker strategy, including mining power, block depth, connectivity, and the impact of eclipse attacks. The MDP was implemented with a cutoff value of 20 blocks, representing an attack of finite duration. Via a search

algorithm over the space defined by the MDP, and in combination with a simulation of a blockchain system that determined for example block propagation times and throughput, they determined the maximum transaction value that would be safe from double spending by an economically rational attacker. This approach is rich, capturing the optimal strategy for double-spending (as well as selfish mining [7,16]) given network conditions and blockchain parameters. Gervais et al. were able to reach many fascinating conclusions about the comparative performance and security of several widely used blockchains.

Double spending. A fundamental attack against Bitcoin is the double-spend attack [13], which works as follows. An attacker creates a transaction that moves funds to a merchant's address. After the transaction appears in the newest block on the main branch, the attacker takes possession of the purchased goods. Using his mining power, the attacker then immediately releases two blocks, with a transaction in the first that moves the funds to a second attacker-owned address. Now the attacker has the goods and his coin back. To defend against the attack, a merchant can refuse to release goods to a Bitcoin-paying customer until z blocks have been added to the blockchain including the first block containing a transaction moving coin to the merchant's address. Nakamoto calculated the probability of the attack succeeding assuming that the miner controlled a given fraction of the mining power [13]; for a given fraction, the probability of success decreases exponentially as z increases.

In general, a merchant may wait z blocks before releasing goods, which can thwart an attacker. But choosing the minimum value of z that secures a transaction is an unresolved issue. The core Bitcoin client shows that a transaction is unconfirmed until it is 6 blocks deep in the blockchain [2], and advice from others is necessarily vague; e.g., "for very large transactions, coin owners might want to wait for a larger number of block confirmations" [4].

#### 4.1.2 Related Work

The standard Bitcoin protocol requires miners to broadcast a block they mined immediately. However, in the case of selfish mining, a miner purposefully withholds his blocks. The motivation is to bifurcate the chain and waste the computational resources of the honest miners should the network decide to build on the attacker's chain. An attacker can not profit economically since the number of blocks that can be created by a miner depends on the fraction of the mining power he has. However, selfish mining discards the honest miners' blocks, by releasing an alternative chain that takes over the current longest chain. If a selfish mining attack is successful, the selfish miners own a higher fraction of the blocks on the main chain because some portion of the blocks created by the honest network go to waste.

Eyal et al. [7] modeled selfish mining using a Markov chain. Then Sapirshtein et al. [16] created a more complex model using a Markov decision process (MDP) for selfish mining and computed the  $\epsilon$ -optimal policy that increases a selfish miner's revenue. Recently, Gervais et al. [9] incorporated additional parameters such as network conditions and Bitcoin settings into the MDP to study the affects of such parameters on the attacker's policy.

Sapirshtein et al. [16] first observed that some double-spend attacks can be carried out essentially cost-free in the presence of a concurrent selfish mining [7] attack. More recent work extends the scope of double-spends that can benefit from selfish mining to cases where the attacker is capable of pre-mining blocks on a secret branch at little or no opportunity cost [17]. The papers identify the optimal mining strategy for an attacker and quantify the advantage that he can expect to have over the merchant in terms of pre-mined blocks. This analysis is complementary to ours; it is possible to relatively easily incorporate the pre-mining advantage into our model by simply changing the attacker's block target from z to z - c. We note that pre-mining in the context of the eclipse attack may not be feasible since an eclipse cannot generally be

carried out for an indefinite period of time. Nevertheless, we intend to update both of our double-spend analyses to account for cost-free pre-mining in future work.

Gervais et al. [9] is the work most directly related to our objectives. Rosenfeld [14] also has the same economic objective. As we discuss in Section ??, in general, the approach taken by past work, including Gervais et al., Rosenfeld, and the works cited above, models only the *order* of block creation, which is a discrete process; they do not model block mining time, which is a continuous process. As a result, it is difficult to extend those results to model cost in circumstances where the attacker is given a specific deadline in time (as we have done in our eclipse attack analysis) or where an attacker drops out (because the honest miners have already won) but has spent time mining. We develop a richer, continuous-time model that explicitly accounts for attacker cost as a function of mining duration.

#### 4.2 Problem Statement

In this project, we study a form of adversarial behavior in cryptocurrencies. Known as selfish mining, this behavior involves the deliberate withholding of transaction information. We study whether an attacker who wants to perform selfish mining could use a reinforcement learning method to search for the optimal strategy. Furthermore, we compare the optimal policy found by RL algorithms to those cited in previous work.

**Parametrization of**  $\beta$ . Let  $X = X_1, \dots, X_n$ , where  $X \sim \text{Exp}(\beta)$ , where  $\beta = 1/\lambda$ . The MLE estimator for  $\beta$  is

$$\hat{\beta} = \frac{\sum_{i=1}^{n} X_i}{n} \tag{4.1}$$

The expected value of the estimator is

$$\mathbb{E}[\hat{\beta}|\beta] = \frac{1}{n} \mathbb{E}\left[\sum_{i=1}^{n} X_i\right]$$
(4.2)

$$=\frac{1}{n}n\beta\tag{4.3}$$

$$=\beta \tag{4.4}$$

This estimator *not* biased. The bias is

$$\operatorname{bias}(\hat{\beta}) = \mathbb{E}[\hat{\beta}|\beta] - \beta \tag{4.5}$$

$$= \beta - \beta \tag{4.6}$$

$$=0 (4.7)$$

The variance of the estimator is

$$Var(\hat{\beta}) = Var\left(\frac{\sum_{i=1}^{n} X_i}{n}\right)$$
(4.8)

$$= \frac{1}{n^2} \operatorname{Var}\left(\sum_{i=1}^n X_i\right) \tag{4.9}$$

$$=\frac{1}{n^2}n\beta^2\tag{4.10}$$

$$=\frac{1}{n}\beta^2\tag{4.11}$$

Ideally, in Bitcoin  $\beta = 1/10$  mins and in Ethereum  $\beta = 1/15$  secs. Note that the variance increases with more data (more inter-arrival times).

Understanding the Relationship Between Hash Rate and  $\beta$ . Given target  $T_i$ , the expected number of hashes, h, needed to meet the target for a block is

$$\mathbb{E}[h] = \frac{2^{256} - 1}{T_i} \tag{4.12}$$

However,  $\mathbb{E}[h]$  describes the *total* number of expected hashes needed to find a block. We have observations regarding the *time* it takes to generate a block. Let r be the hash rate of the network in minutes (or the number of hashes per time unit), and  $X = X_1, \ldots, X_n$ , where  $X \sim \text{Exp}(\beta)$ , where  $\beta = 1/\lambda$ . Note that  $\lambda r$  is the expected number of hashes each time a block is created.

$$\mathbb{E}[h] = r\lambda = r\frac{1}{\beta} \tag{4.13}$$

$$r = \mathbb{E}[h]\beta \tag{4.14}$$

#### Expected Value of Hash Rate.

$$\mathbb{E}[r|T_i, X_1, ..., X_n] = \mathbb{E}\left[\frac{(2^{256} - 1)\hat{\beta}}{T_i}\right]$$
(4.15)

$$= \frac{(2^{256} - 1)}{T_i} \mathbb{E}[\hat{\beta}] \tag{4.16}$$

$$=\frac{(2^{256}-1)\beta}{T_i}\tag{4.17}$$

#### Variance of Hash Rate.

$$\operatorname{Var}(r|T_i, X_1, ..., X_n) = \operatorname{Var}\left(\frac{(2^{256} - 1)\hat{\beta}}{T_i}\right)$$
 (4.18)

$$= \frac{(2^{256} - 1)^2}{T_i^2} \text{Var}(\hat{\beta})$$
 (4.19)

$$=\frac{(2^{256}-1)^2\beta^2}{T_i^2n}\tag{4.20}$$

#### Bias of Hash Rate.

$$bias(r|T_i, X_1, ..., X_n) = \mathbb{E}[r|T_i, X_1, ..., X_n] - r$$
(4.21)

$$=\frac{(2^{256}-1)\beta}{T_i} - \frac{(2^{256}-1)\beta}{T_i}$$
 (4.22)

$$=0 (4.23)$$

The variance for estimating the miner hash rate is huge! You'd require more blocks than those that are in the blockchain to reduce variance! Therefore, let's use RL.

**Example.** The current Bitcoin difficulty,  $D_i$ , is  $1,590,896,927,258 \approx 2^{40}$ . This means the current target,  $T_i$ , is

$$T_i = \frac{2^{224}}{D_i} = \frac{2^{224}}{2^{40}} \tag{4.24}$$

$$\approx 2^{184} \tag{4.25}$$

Then approximately the variance associated with the hash rate is

$$Var(r|T_i, X_1, ..., X_n) = \frac{(2^{256} - 1)^2 \beta^2}{T_i^2 n}$$
(4.26)

$$\approx \frac{(2^{256})^2 \beta^2}{T_i^2 n} \tag{4.27}$$

$$\approx \frac{(2^{256})^2 \beta^2}{(2^{184})^2 n} \tag{4.28}$$

$$\approx \frac{2^{512}\beta^2}{2^{368}n} \tag{4.29}$$

$$\approx 2^{144} \frac{\beta^2}{n} \tag{4.30}$$

A huge number no matter what  $\beta$  or n is!

#### 4.3 Preliminary Work

#### 4.3.1 Formulating the Problem as an MDP

**States.** Using Sapirshtein et al. [16]'s model as a basis, we construct the following MDP that is a 6-tuple  $\{S, A, P, R, \gamma, d_0\}$ , where  $S = \{(x, y, z)\}$  such that  $x, y, z \in \mathbb{N}$ . The state consists of a 3-tuple where x denotes the number of blocks on the attacker's hidden chain, y denotes the number of blocks created by the honest miners on the main chain, and z denotes the number of blocks that the attacker released on the

main chain. Note that this representation assumes that all blocks build on the same parent block.

Actions.  $A = \{adopt, mine, override, match\}$ . adopt refers to the adoption of the main chain, thereby discarding all blocks created by the attacker. The action mine denotes that the attacker continues to mine, waiting to see who the next block will be discovered by. override refers to an attacker's releasing one more block than the honest miners' blocks on the main chain. This action can be viewed as honest or selfish depending on the current state. If the honest miners have no blocks on the main chain, an addition of a block to the main chain means that the attacker is honest. However, if the honest miners already have blocks on the main chain and the attacker releases an alternative chain that is 1 block longer than that created by the honest miners, then the attacker overwrites the main chain, wasting the victim's computational resources. The match action means that the attacker releases as many blocks as there are on the main chain, causing a bifurcation.

Initial state distribution.  $d_0 = \{(0,0,0)\}$ , where  $P(S_0 = (0,0,0)) = 1$ . In other words, the start state assumes that no blocks have been mined yet. When the attacker chooses the action adopt, the agent goes back to the start state because a new parent block is chosen to build on top of.

**Transition Function.** We consider 3 of parameters of interest included in Gervais et al. [9]'s model. At each time step, a new block is created by the network: with probability q, where q is the mining power of the attacker, the attacker is the winner of a new block. The honest network discovers a block with probability 1 - q. Not all actions are available in every state. The attacker can always choose the mine action. The adopt action is only available when there are blocks on the main chain created by the honest network. Additionally, override and match are only available when the attackers have enough blocks. At cutoff, c = 30, we force the attacker to choose the adopt action in order to have episodic trials. If the number of blocks created by

the honest miners exceeds those of the attacker by c, we force the attacker to end the episode. Our third parameter, a, represents network connectivity. If there is a fork of same length on the main chain, fraction a of the honest miners build on the attacker's alternative chain. We set a=1 to give advantage to the attacker, and to see if RL methods can learn to take advantage of the match action. If the attacker matches the main chain with a fork of the same length, all honest miners build on the attacker's chain.
